Abstract

Background: Human immunodeficiency virus (HIV) infection leads to more rapid progression of hepatitis C virus (HCV)-related liver fibrosis, which could be linked to differences in the severity of liver inflammation among HIV/HCV co-infected individuals compared to HCV mono-infected individuals.
This study assessed the association of HIV co-infection with pro-inflammatory and pro-fibrogenic cytokines and chemokines during recent HCV infection.

Methods: Participants from the ATAHC study, a prospective cohort of recent HCV infection, with detectable HCV RNA at the time of acute HCV detection were included. Concentrations of 27 plasma cytokines and chemokines were measured by multiplex immunoassays and compared between those with, and without, HIV co-infection.

Results: Out of 117 individuals with recent HCV infection included in analysis, 73 had HCV mono-infection and 44 had HIV/HCV co-infection. Individuals with HIV/HCV co-infection had significantly higher mean levels of eotaxin (1.79 vs. 1.62 log pg/mL; $P < 0.001$), monocyte chemotactic protein 1 (MCP-1; 2.10 vs. 1.98 log pg/mL; $P < 0.001$), and interferon-gamma inducible protein-10 (IP-10; 3.11 vs. 2.98 log pg/mL; $P = 0.013$). Linear regression analyses adjusting for age, alanine transaminase (ALT), HCV RNA levels, and assay run, higher eotaxin levels were independently associated with HIV/HCV co-infection (adjusted β: 0.12; 95%CI: 0.01, 0.24; $P = 0.039$). Higher MCP-1 levels were also independently associated with HIV/HCV co-infection in adjusted analysis (adjusted β: 0.11; 95%CI: 0.03, 0.18; $P = 0.009$).

Conclusions: During recent HCV, those with HIV/HCV co-infection had a stronger pro-fibrogenic mediator profile compared to those with HCV mono-infection. These findings may provide a potential explanation for accelerated liver fibrosis in HIV/HCV co-infection.

Trial registration: Australian Trial in Acute Hepatitis C (ATAHC) study was registered with ClinicalTrials.gov registry on September 11, 2005. NCT00192569.

Background

Among people with chronic hepatitis C virus (HCV) infection, co-infection with human immunodeficiency virus (HIV) leads to accelerated liver fibrosis progression [1–5]. Several mechanisms have been suggested, including increased pro-fibrogenic cytokine expression and secretion, enhanced oxidative stress, increased hepatocyte apoptosis, and immunosuppression [1, 6–8], although there is no clear consensus.

One potential explanation for more rapid fibrosis progression among HIV/HCV co-infected individuals compared to HCV mono-infected individuals could be differences in the severity of hepatic inflammation, leading to fibrosis. In the setting of chronic HCV infection, it has been demonstrated that individuals with HIV/HCV co-infection have higher levels of a number of pro-inflammatory cytokines and chemokines [9, 10]. Further, it has been shown that intrahepatic mRNA levels of inflammatory cytokines are higher among people with HIV/HCV co-infection as compared to HCV mono-infection [11]. In the setting of acute HCV infection, it has previously been demonstrated that higher levels of interferon-gamma inducible protein-10 (IP-10) levels are observed among people with HIV, compared to those without HIV infection [12]. However, there are little data evaluating other cytokine and chemokine levels in people with, and without, HIV co-infection with recent HCV infection.

The Australian Trial in Acute Hepatitis C (ATAHC) was a multicentre, prospective cohort study of the natural history and treatment of recent (acute and early chronic) HCV infection [13]. The aim of this study was to compare cytokine and chemokine levels in people with, and without, HIV co-infection who acquired HCV infection.

Methods

Study participants

In ATAHC, acute or early chronic HCV infection was defined by an initial positive anti-HCV antibody test within 6 months of enrolment and either 1) a negative anti-HCV antibody test within 2 years prior to the initial positive anti-HCV antibody test or 2) acute clinical hepatitis within 12 months before the initial positive anti-HCV antibody result. Acute clinical infection was defined by symptomatic seroconversion illness or peak alanine transaminase (ALT) level greater than 400 IU/mL at or before the time of HCV diagnosis. In the current study, ATAHC participants with available plasma samples and HCV RNA detected at the time of acute HCV detection (screening visit) were included. Cytokines and chemokines were measured in screening visit plasma samples using a multiplex assay (see below).

Measurement of plasma cytokines and chemokines

Three human cytokine multiplex bead array assay kits utilizing technology licensed by Luminex (Bio-Rad, Gladesville, Australia) measured the following cytokines and chemokines: interleukin-1b (IL-1b), IL-4, IL-6, IL-10, IL-17A, IL-17F, IL-21, IL-22, IL-23, IL-25, IL-31, IL-33, interferon-gamma (IFN-g), soluble CD40 ligand (sCD40L), tumor necrosis factor alpha (TNF-a), (with Bio-Plex human TH17 15-plex), IL-2, IL-8, eotaxin-1 (or CCL11), IFN-g, interferon-gamma inducible protein-10 (IP-10, or CXCL10), monocyte chemotactic protein 1 (MCP-1, or CCL2), macrophages inflammatory proteins 1 alpha (MIP-1a, or CCL3), MIP-1ß (or CCL4), RANTES (regulated upon activation normal T-cell expressed, and presumably secreted; or CCL5) (with Bio-Plex human cytokine Group I 9-plex) and IL-18, TNF-ß, TNF-related apoptosis-inducing ligand (TRAIL, or TNFSF10) (with Bio-Plex human cytokine Group II 3-plex).

The protocol was performed as per the manufacturer's instructions and previously described [14, 15]. Samples were centrifuged at 10,000 x g for 10 min at 4 °C to remove platelets and precipitates, after which the supernatants were diluted four times with assay diluents. The assay was performed using all the assay components provided in a 96-well filter plate. The raw data was analysed using the Bio-Plex Manager software, v6.1 (Bio-Rad) [16].

Statistical analysis

Log_{10} transformed values of cytokines levels (log_{10} pg/mL) were used in analysis given the distribution of the actual values were not normal. The mean of plasma cytokine levels were compared between individuals with and without HIV co-infection (Student T test). If the plasma cytokine level was below the level of detection, the midpoint between zero and the lowest level of reliable detection was imputed (Additional file 1: Table S1). Plasma levels of four cytokines (IL-23, IFN-g, TNF-b, and MIP-1a) were undetectable in ≥20 % of individuals, for which proportion of individuals with undetectable cytokine level was compared between individuals with, and without, HIV co-infection (Chi-squared test).

Overall, 27 comparisons of plasma cytokines levels were conducted between two groups of individuals with, and without, HIV co-infection. Whether adjustments are needed for multiple comparisons is a matter of controversy given that multiple comparison testing might inflate type 1 error while adjustments for multiple comparisons inflate type 2 error [17–20]. To account for multiple comparisons, a moderately conservative significance level ($alpha$ = 0.01) was used. In a sensitivity analysis, using Bonferroni correction for multiple

Lamoury *et al. BMC Infectious Diseases* (2016) 16:241

Page 3 of 9

comparisons, an $alpha = 0.05/27 = 0.002$ was also used, but the findings were similar.

Two cytokines (i.e., MCP-1 and eotaxin) which had significantly different means between individuals with, and without, HIV co-infection were included in linear regression analysis. Linear regression models were fitted to assess the association of HIV co-infection with each plasma cytokine levels (log pg/mL). In the adjusted models, the association of these two cytokines and HIV co-infection was adjusted for potential confounders including age, ALT levels, and HCV RNA level at the time of acute HCV detection. Potential confounders were the variables associated with either HIV status or plasma cytokine levels in this study. To account for potential unmeasured confounders introduced by different assay runs and sample set, the models were also adjusted for assay set. All analyses were performed using Stata v12.0 (College Station, TX, United States).

Results

Participant characteristics

A total of 117 individuals with recent HCV infection were included in the study, including 44 (38 %) with and 73 without (62 %) HIV co-infection. Background characteristics of the study population are summarized in Table 1. All individuals with HIV co-infection were male. Compared to individuals without HIV, those with HIV co-infection were significantly older, had a higher ALT level and had a greater proportion with high HCV RNA levels (≥400,000 IU/mL) at the time of recent HCV detection (Table 1). Two participants had HBV co-infection (positive HBsAg), both with no HIV co-infection.

Among 44 individuals with HIV co-infection, 24 (55 %) had HIV viral suppression (≤50 IU/ml) at the time of recent HCV detection. Among those with no HIV viral suppression, the median HIV RNA levels at the time of recent HCV detection was 4400 IU/mL (inter quartile range: 400, 33467). CD4 count at the time of acute HCV detection was ≥500 cells/μL in 28 (64 %) individuals, and 200–499 cells/μL in 14 (32 %) individuals (not available in two individuals). Thirty-three individuals (75 %) were on antiretroviral therapy at the time of acute HCV detection, among whom, 18 (55 %) had HIV viral suppression.

During the follow-up, ten individuals (9 %) cleared HCV spontaneously, while 107 individuals (91 %) either progressed to chronic infection, or received treatment.

Distribution of cytokines levels by HIV status

The distribution of cytokine levels in individuals with, and without, HIV co-infection is summarized in Table 2. Individuals with HIV co-infection had significantly higher mean plasma levels of MCP-1 and eotaxin

[standard deviation (SD): 0.21] and 1.78 log pg/mL (SD: 0.19), respectively, which were comparable to 2.09 log pg/mL (SD: 0.18) and 1.83 log pg/mL (SD: 0.27), respectively among those with CD4 count 200–499 cells/μL ($P = 0.627$ and $P = 0.524$, respectively).

In another analysis, the association of estimated of duration of HCV infection at the time of HCV detection with plasma cytokines levels were assessed (Additional file 1: Table S4). The mean plasma levels of IL-2 was significantly higher in individuals with an estimated of duration of HCV infection ≥26 weeks (1.07 log pg/mL; SD: 0.08) compared to those with an estimated of duration of HCV infection <26 weeks (1.15 log pg/mL; SD: 0.15; $P = 0.001$).

Discussion

This study assessed the association of plasma cytokine and chemokine levels with HIV co-infection among individuals with recent HCV infection. HIV/HCV co-infection was independently associated with higher plasma levels of two pro-inflammatory and pro-

fibrogenic chemokines, MCP-1 and eotaxin. Increased plasma levels of MCP-1 and eotaxin in HIV/HCV co-infection might reflect increased hepatic expression of these cytokines and a subsequent chronic pro-inflammatory response [21, 22].

Individuals with HIV/HCV co-infection and recent HCV infection in this study had significantly higher MCP-1 plasma levels compared to those with HCV mono-infection, which is consistent with findings in the setting of chronic HCV infection [9]. Similar findings in the setting of recent HCV infection are important and suggest that elevated levels of MCP-1 in HIV/HCV co-infected individuals occur early following HCV infection. A previous study has shown that MCP-1 plasma levels were elevated in HIV infection and correlated with HIV RNA levels [23]. However, MCP-1 plasma levels in the current study were comparable between HIV co-infected individuals with and without HIV viral suppression.

C-C chemokine receptor 2 (CCR2) and its main ligand MCP-1 (CCL2) have major roles in promoting the accumulation and activation of monocyte-macrophages in

the inflamed liver, as well as the activation of hepatic stellate cells (HSC) which are key drivers of fibrosis (reviewed in [24]). The role of CCR2 in promoting HSC chemotaxis and the development of hepatic fibrosis has been shown in animal models [25]. In humans, increased MCP-1 expression and CCR2-dependent macrophage infiltration in the liver [26, 27], and also higher MCP-1 plasma levels [28] have been found in the fibrotic liver. An MCP-1 gene polymorphism has been associated with increased expression of MCP-1 in the liver among individuals with chronic HCV and those with more advanced fibrosis [29]. In one longitudinal study, more rapid progression of hepatic fibrosis in HCV infection was correlated with persistent and significant elevation of MCP-1 plasma levels from acute to chronic infection [30]. Taken together, these data indicate the critical role of MCP-1 in development and progression of liver fibrosis. This existing evidence, coupled with our findings of increased MCP-1 plasma levels in HIV/HCV co-infection suggest a potential explanation for accelerated liver fibrosis progression in HIV/HCV co-infection,

compared to HCV mono-infection. This hypothesis is supported by the in vitro data indicating that HIV can infect activated hepatic stellate cells (HSCs) to induce secretion of MCP-1 [31].

Knockout of CCR2 in mice results in reduced MCP-1 expression, diminished monocyte/macrophage infiltration and the development of lower levels of fibrosis following liver injury [32]. Further, data from animal models indicate that inhibition of MCP-1 reduces intrahepatic macrophage accumulation and development of steatohepatitis [21, 33]. Recently, Cenicriviric, a CCR2 and CCR5 antagonist, demonstrated good efficacy in suppressing HIV in phase IIb clinical trials [34, 35]. In addition to the antiretroviral effects, in animal models, Cenicriviric is anti-fibrotic, and reduces liver fibrosis progression [36]. One hypothesis is that the inhibition of MCP-1 might have therapeutic potential in reducing liver fibrosis progression in individuals with HIV/HCV co-infection. This hypothesis is required to be supported by further research to evaluate the potential effect of inhibiting MCP-1 in reducing liver fibrosis.

Lamoury et al. BMC Infectious Diseases (2016) 16:241

Page 7 of 9

Individuals with HIV/HCV co-infection and recent HCV infection in this study also demonstrated higher plasma eotaxin levels compared to those with HCV mono-infection. Eotaxin (CCL11) is a chemokine originally known as an eosinophil-specific chemoattractant which regulates eosinophil trafficking and facilitates eosinophil migration into the tissue by activating CCR3 receptors (reviewed in [37, 38]). Up-regulation of eotaxin expression has been demonstrated in the liver of individuals with drug-induced hepatitis and is accompanied by liver infiltration of eosinophils [39]. In the setting of HCV infection, increased plasma levels of eotaxin have been demonstrated in individuals with chronic HCV infection compared with healthy controls [40], while development of persistent HCV has also been found to be associated with higher plasma levels of eotaxin during acute infection [41]. Moreover, eotaxin has a role in hepatic fibrogenesis. Higher plasma eotaxin levels have been identified among individuals with liver cirrhosis, with higher eotaxin levels associated with increasing stage of fibrosis, and hepatic necro-inflammation and fibrosis by liver histology [42]. The observation that higher eotaxin plasma levels are observed in those with HIV/HCV co-infection suggest that, similar to MCP-1, eotaxin might have a role in explaining accelerated liver fibrosis in individuals with HIV/HCV co-infection.

This study had several limitations. First, this dataset was cross-sectional, then it was not possible to measure longitudinal levels of cytokines during acute HCV infection. Further, cytokine and chemokine concentrations were measured from plasma samples, so it is possible that the levels in the blood might not reflect hepatic levels. However, it has been demonstrated that intrahepatic and peripheral sources of MCP-1 are known to both contribute to elevated serum MCP-1 concentrations [22]. Data on liver fibrosis levels was not available in our participants. Further studies are needed to investigate the role of high MCP-1 and eotaxin levels in liver fibrosis progression among HIV/HCV co-infected individuals. Lastly, multiple comparison testing might inflate type 1 error in data analysis. To account for this concern, a moderately conservative significance level ($alpha = 0.01$) was used. We also conducted a sensitivity analysis, using Bonferroni correction for multiple comparisons ($alpha = 0.05/27 = 0.002$) but the findings were similar.

Conclusion

In conclusion, this study has demonstrated that compared to those without HIV infection, following acute HCV infection among people with HIV-infection, increased levels of the pro-fibrogenic chemokines, MCP-1 and eotaxin were observed. These findings could suggest a potential pathway possibly linking HIV infection with liver fibrogenesis among people with HIV/HCV infection. These findings may have also potential implications for therapeutic interventions to prevent liver fibrosis in people with HIV/HCV co-infection.

Additional file

Additional file 1: Table S1. The lowest level of detection for measurement of plasma cytokine and chemokine levels. **Table S2.** Unadjusted and adjusted models assessing the association of HIV co-infection with plasma MCP-1 levels among males in ATAHC (n=88). **Table S3.** Unadjusted and adjusted models assessing the association of HIV co-infection with plasma eotaxin level among males in ATAHC (n=88). **Table S4.** Plasma cytokine and chemokine levels among ATAHC participants with detectable HCV RNA at the time of acute HCV detection, stratified by estimated duration of HCV infection at the time of HCV detection. (DOCX 32 kb)

Availability of data and materials

Additional data are available as supplementary materials. All raw data are available by request to corresponding authors.

Authors' contributions

GJD, GVM, MH, and ARL designed the original ATAHC study and wrote the protocol. BH, FMJL, JG, TLA, GJD, JJF, and ARL designed the current study. GJD, GVM, JG, BH ARL and ST provided samples and clinical data. FMJL and EK performed all laboratory work with input from TLA. BH and FMJL drafted the primary analysis plan, which was reviewed by JG, TLA, and JA. The primary analysis was conducted by BH which was reviewed by JG and JA. BH, FMJL, JG, and TLA wrote the first draft of the article. All authors contributed to and approved the final article.

Competing interests

The authors declare that they have no competing interests.

Consent to publish

Not applicable.

Ethical approval

The ATAHC protocol was reviewed and approved by Human Research Ethics Committees of St. Vincent's Hospital, Sydney and the University Health Network, and all patients provided informed written consent. The study was registered with clinicaltrials.gov registry (NCT00192569). This study on chemokines and cytokines has been specifically approved by the St Vincent's Hospital Human Research Ethics Committee (HREC ref#HCV12612. LNR/12/SVH/223).
